## ABSTRACT

We report 4.5  $\mu\text{m}$  luminosities for 27 nearby ( $D \lesssim 5$  Mpc) dwarf irregular galaxies measured with the *Spitzer* Infrared Array Camera. We have constructed the 4.5  $\mu\text{m}$  luminosity-metallicity ( $L$ – $Z$ ) relation for 25 dwarf galaxies with secure distance and interstellar medium oxygen abundance measurements. The 4.5  $\mu\text{m}$   $L$ – $Z$  relation is  $12+\log(\text{O}/\text{H}) = (5.78 \pm 0.21) + (-0.122 \pm 0.012) M_{[4.5]}$ , where  $M_{[4.5]}$  is the absolute magnitude at 4.5  $\mu\text{m}$ . The dispersion in the near-infrared  $L$ – $Z$  relation is smaller than the corresponding dispersion in the optical  $L$ – $Z$  relation. The subsequently derived stellar mass-metallicity ( $M_*$ – $Z$ ) relation is  $12+\log(\text{O}/\text{H}) = (5.65 \pm 0.23) + (0.298 \pm 0.030) \log M_*$ , and extends the SDSS  $M_*$ – $Z$  relation to lower mass by about 2.5 dex. We find that the dispersion in the  $M_*$ – $Z$  relation is similar over five orders of magnitude in stellar mass, and that the relationship between stellar mass and interstellar medium metallicity is similarly tight from high-mass to low-mass systems. We find a larger scatter at low mass in the relation between effective yield and total baryonic mass. In fact, there are a few dwarf galaxies with large yields, which is difficult to explain if galactic winds are ubiquitous in dwarf galaxies. The low scatter in the  $L$ – $Z$  and  $M_*$ – $Z$  relationships are difficult to understand if galactic superwinds or blowout are responsible for the low metallicities at low mass or luminosity. Naively, one would expect an ever increasing scatter at lower masses, which is not observed.

*Subject headings:* galaxies: dwarf — galaxies: evolution — galaxies: irregular — infrared: galaxies

## 1. INTRODUCTION

The luminosity-metallicity ( $L$ – $Z$ ) relation for gas-rich star-forming galaxies is a robust relationship which holds over ten magnitudes in galaxy optical luminosity (e.g., Zaritsky et al. 1994; Tremonti et al. 2004). The physical basis for this relation has generally been attributed to a mass-metallicity relation for galaxies. The  $L$ – $Z$  relation has also become an important tool to examine the time-evolution of past chemical enrichment and the (stellar) mass-metallicity ( $M_*$ – $Z$ ) relation for more massive galaxies at distant epochs, where emission lines at rest-frame optical wavelengths are redshifted into the near-infrared; see, e.g., Kobulnicky & Zaritsky (1999); Kobulnicky et al. (2003); Liang et al. (2004); Kobulnicky & Kewley (2004); Shapley et al. (2004); Gallazzi et al. (2005); Hoyos et al. (2005); Maier et al. (2005); Savaglio et al. (2005); Shapley et al. (2005); Erb et al. (2006); Lamareille et al. (2006); Liang et al. (2006). The growing body of observations at intermediate- and high-redshifts has led to work on a variety of galaxy formation models and their subsequent predictions for  $L$ – $Z$  and  $M_*$ – $Z$  relations (e.g., Somerville & Primack 1999; Bell & Bower 2000; Tamura et al. 2001; Dekel & Woo 2003; De Lucia et al. 2004; Savaglio et al. 2005; Tissera et al. 2005).

For nearby dwarf irregular and other star-forming dwarf galaxies, the corresponding  $L$ – $Z$  relation has traditionally been studied at optical wavelengths (e.g., Lequeux et al. 1979; Skillman et al. 1989; Richer & McCall 1995; Skillman et al. 1997; Pilyugin 2001; Garnett 2002; Hidalgo-Gómez et al. 2003; H. Lee et al. 2003a,b,c; Pilyugin et al. 2004; van Zee & Haynes 2006; van Zee et al. 2006). If systematic uncertainties are minimized, the resulting residuals

in the  $L$ – $Z$  relation can be used to examine effects of galaxy evolution (e.g., Kobulnicky et al. 2003). However, dispersion in the optical  $L$ – $Z$  relation is thought to arise from variations in the stellar mass-to-light ratios, which are caused by variations in the current star formation rate (SFR) among galaxies (see, e.g., Bell & de Jong 2001; Tumlinson 2006). To minimize the effects of these variations, the  $L$ – $Z$  relation can be determined at near-infrared (NIR; 1–5  $\mu\text{m}$ ) wavelengths, where the dominant emission arises from the stellar populations.

Recent ground-based efforts to determine  $L$ – $Z$  and  $M_*$ – $Z$  relations for low-mass systems in the NIR have been constructed and described by, e.g., Pérez-González et al. (2003), J. Lee et al. (2004), Salzer et al. (2005), Saviane et al. (2005), Oliveira et al. (2006), and Rosenberg et al. (2006). The sensitivity of the *Spitzer Space Telescope* provides an excellent opportunity to observe total emission from the stellar populations in nearby dwarf galaxies, because most of these systems are of intrinsically low surface brightness, and are therefore highly challenging to observe in the NIR from the ground (e.g., Vaduvescu et al. 2005). The 4.5  $\mu\text{m}$  luminosities are dominated by emission from stellar photospheres (e.g., Lu et al. 2003; Dale et al. 2005; Galliano 2005), and are less sensitive to bursts of star formation. Observations at 4.5  $\mu\text{m}$  were chosen also because the passband was designed to avoid emission from polycyclic aromatic hydrocarbons (PAHs; e.g., Léger & Puget 1984; Allamandola et al. 1985). PAH emission does not appear to be significant within lower-luminosity metal-poor galaxies (e.g., Houck et al. 2004; Engelbracht et al. 2005; Hogg et al. 2005). Although emission from hot dust might be significant in disk galaxies at 4.5  $\mu\text{m}$  (e.g., Roussel et al. 2005), our 8  $\mu\text{m}$  observations have shown that the contributions from PAHs and warm dust are not significant in our sample of low-mass dwarf galaxies (Jackson et al. 2006).

In light of the  $M_*$ – $Z$  relation for massive galaxies determined by Tremonti et al. (2004), we consider nearby dwarf

<sup>1</sup> Department of Astronomy, University of Minnesota, 116 Church St. S.E., Minneapolis, MN 55455; hlee, skillman, djackson, gehrz, elwood, chelsea@astro.umn.edu

<sup>2</sup> Max-Planck-Institut für Astronomie, Königstuhl 17, D-69117 Heidelberg, Germany; cannon@mpia.de

galaxies, which extend the mass range down by roughly 2.5 dex. This allows us to examine the  $M_*$ - $Z$  relation over five orders of magnitude in stellar mass. To construct the  $L$ - $Z$  and  $M_*$ - $Z$  relations at  $4.5\ \mu\text{m}$ , we have chosen nearby star-forming dwarf irregular galaxies that have distances measured from stellar constituents, and oxygen abundances derived from high-quality spectra (namely, [O III]  $\lambda 4363$  measurements). We have assembled a sample of 27 dwarf galaxies at distances below about 5 Mpc; some properties of these dwarf galaxies are listed in Table 1.

The remainder of this paper proceeds as follows. Those who wish to skip the details should go directly to § 7, where we interpret our key results in the context of the findings by Tremonti et al. (2004). Observations and reductions of the data are presented in § 2. We describe the measurements of flux densities and absolute magnitudes of dwarf galaxies at  $4.5\ \mu\text{m}$ , and the corresponding NIR  $L$ - $Z$  and  $M_*$ - $Z$  relations in §§ 3 and 4. We have also gathered from the literature other  $L$ - $Z$  and  $M_*$ - $Z$  relations for local and distant star-forming galaxies. As all of the galaxies in our sample have direct measurements of their H I gas, we also examine relations with gas-to-stellar mass ratio and H I rotation velocity in §§ 5 and 6, respectively. We give additional discussion and a summary in §§ 7 and 8, respectively. For the present discussion, we use the notation  $[\text{O}/\text{H}] = \log(\text{O}/\text{H}) - \log(\text{O}/\text{H})_\odot$ , where the solar value of the oxygen abundance is  $12 + \log(\text{O}/\text{H}) = 8.66$  (Asplund et al. 2004; Meléndez 2004). We adopt  $Z_\odot = 0.0126$  as the revised solar mass fraction in the form of metals (Asplund et al. 2004).

## 2. OBSERVATIONS AND REDUCTIONS

Data were acquired with the Infrared Array Camera (IRAC; Fazio et al. 2004) on the *Spitzer Space Telescope* (Werner et al. 2004) during the first year of nominal operations from 2003 December to 2004 December. In Guaranteed Time Observation (GTO) program 128 (P.I. R.D. Gehrz), ten galaxies were imaged in channels 2 ( $4.5\ \mu\text{m}$ ) and 4 ( $8\ \mu\text{m}$ ). The Astronomical Observation Request Key (AORKEY) for each galaxy is listed in Table 1. We performed five dither positions per pointing with exposure times of 200 seconds each, except for NGC 55 and WLM which had exposure times of 100 seconds per dither position. A single  $5' \times 5'$  pointing was used for all targets, except for IC 1613, NGC 55, NGC 3109, and WLM, which were mosaicked in array coordinates using a  $2 \times 2$  ( $10' \times 10'$ ), a  $1 \times 2$  ( $5' \times 10'$ ), and a  $1 \times 3$  ( $5' \times 15'$ ) pointing grid, respectively. NGC 55 was mosaicked in sky coordinates, resulting in a  $15' \times 10'$  field-of-view. Using the MOPEX<sup>3</sup> reduction package, the final mosaics were created as described in Jackson et al. (2006). These images contained the appropriate astrometry in Epoch J2000 coordinates and were flux-calibrated in units of MJy  $\text{sr}^{-1}$ . Postage-stamp images at  $4.5\ \mu\text{m}$  of ten galaxies from program GTO 128 are shown in Fig. 1; note that the galaxies are displayed with the same isophotal scaling to emphasize the large range in surface brightness.

Total photometry was obtained with the application of elliptical apertures, and adjusting the dynamic range to show the spatial extent of the emission at  $4.5\ \mu\text{m}$ . We also retrieved optical images from NED and the Local Group Survey<sup>4</sup> (Massey et al. 2002), and we “stretched” these images

visually (in intensity scale) in order to discern the outer limit of the optical extent and to compare the spatial extents of the optical and NIR luminosities. Elliptical apertures were constructed to optimize the amount of light measured for each target galaxy. Six to seven circular apertures in the immediate vicinity of the elliptical aperture were used to sample and determine the mean background level surrounding the galaxy. This method benefits from the sampling of both the sky and the foreground stellar contamination. An example is shown in Fig. 2. We used the IRAF<sup>5</sup> task *polyphot* to perform the aperture photometry and measure flux densities. A variety of tests were performed to mask and remove negative pixels, bright foreground stars, and bright pixels caused by “bleeding” from bright stars. Additional experiments (varying the size of the elliptical aperture; increasing the number of circular “background” apertures) were used to test our final photometry results. The subsequent range in derived luminosities falls well within the quoted uncertainties for the distance modulus and the total errors for IRAC flux measurements (see below).

We have also added from the *Spitzer* public data archive eleven dwarf galaxies from the SINGS Legacy program (Kennicutt et al. 2003b), one dwarf galaxy from program GTO 59 (P.I. G. Rieke), and five dwarf galaxies from program GTO 69 (P.I. G. Fazio). To ensure homogeneity in the derived absolute magnitudes at  $4.5\ \mu\text{m}$ , we have performed the same procedure described above to determine total fluxes and luminosities. As shown in Fig. 3, our measured flux densities for the selected SINGS galaxies are consistent with those reported by Dale et al. (2005).

We adopt 10% as the error in the total flux, assuming this is the maximum error of the absolute calibration in channel 2 (Hora et al. 2004). Various image-based corrections (array location dependent photometric correction, pixel-phase correction) in channel 2 are well below the uncertainty in the absolute calibration (Reach et al. 2005), and are not included in this paper. We have applied a correction to account for extended surface brightness by multiplying measured channel 2 fluxes by a factor of 0.937 (Reach et al. 2005) to obtain the appropriate scaled results. With our measured flux densities at  $4.5\ \mu\text{m}$ , we derived absolute magnitudes,  $M_{[4.5]}$ , by using the adopted zero-magnitude flux density,  $F_{[4.5]}^0 = 179.7 \pm 2.6$  Jy (Reach et al. 2005). We have also assumed zero extinction at  $4.5\ \mu\text{m}$  (e.g., Lutz 1999; Indebetouw et al. 2005), and negligible contribution by diffuse H I Brackett- $\alpha$  emission to the overall galaxy flux (e.g., Lu et al. 2003; Lu 2004).

A comparison between  $B$  and  $4.5\ \mu\text{m}$  luminosities is shown in Fig. 4, where  $B$  luminosities corrected for Galactic extinction are taken from Karachentsev et al. (2004). For the remainder of this paper, we will refer to IRAC channel 2 luminosities as “[4.5]”. Galaxy luminosities at  $4.5\ \mu\text{m}$  are also plotted against  $B$ -[4.5] color; no correlation is evident. The mean  $B$ -[4.5] color for our sample in Table 1 is  $2.08 \pm 0.59$ , which is consistent with the range of observed  $B$ - $K$  colors for a sample of nearby late-type dwarf galaxies in 2MASS (Jarrett et al. 2003).

## 3. THE NEAR-INFRARED LUMINOSITY-METALLICITY RELATION

<http://www.lowell.edu/users/massey/lgsurvey.html>

<sup>3</sup> MOPEX is available from the *Spitzer* Science Center at <http://ssc.spitzer.caltech.edu/postbcd/>.

<sup>4</sup> More about the Local Group Survey is found at

<sup>5</sup> IRAF is distributed by the National Optical Astronomical Observatories, which are operated by the Associated Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.

Twenty-five dwarf galaxies in our sample have reported oxygen abundances, and 21 dwarf galaxies have oxygen abundances derived from [O III]  $\lambda 4363$  measurements (Table 1). In the absence of [O III]  $\lambda 4363$ , oxygen abundances for DDO 53, Ho I, and NGC 3109 were derived using the McGaugh (1991) bright-line calibration<sup>6</sup>. We adopt for Peg DIG the oxygen abundance derived by Skillman et al. (1997). We have assumed oxygen abundances are spatially homogeneous in dwarf irregular galaxies (e.g., Kobulnicky & Skillman 1997; Kobulnicky et al. 1997; H. Lee & Skillman 2004; H. Lee et al. 2005, 2006a).

To obtain fits between absolute magnitude and oxygen abundances for our sample of dwarf galaxies in  $B$  and at  $4.5 \mu\text{m}$ , we used the ordinary least squares bisector method (see Akritas & Bershadsky 1996, and references therein). Specifically, these are bivariate least-squares fits with the bisector method incorporating heteroscedastic errors (in both luminosity and oxygen abundance). The two fits are expressed as

$$\begin{aligned} 12 + \log(\text{O}/\text{H}) &= (5.94 \pm 0.27) + (-0.128 \pm 0.017)M_B \quad (1) \\ &= (5.78 \pm 0.21) + (-0.122 \pm 0.012)M_{[4.5]}, \quad (2) \end{aligned}$$

where  $M_B$  is the absolute magnitude in  $B$ , corrected for Galactic extinction (Karachentsev et al. 2004), and  $M_{[4.5]}$  is the absolute magnitude at  $4.5 \mu\text{m}$ , respectively. The fits in  $B$  and  $[4.5]$  are shown in Fig. 5. The slopes, intercepts, and their corresponding errors are computed with the bi-variate correlated errors and scatter regression code<sup>7</sup>, where we have assumed uncorrelated errors and set the covariance to zero. The resulting errors incorporate uncertainties associated with the data points being fitted. All of the fits below use the same technique, and we refer to this procedure as the “bisector” method<sup>8</sup>. The fit at  $B$  is consistent with similar fits obtained by, e.g., H. Lee et al. (2003b), van Zee & Haynes (2006), and van Zee et al. (2006). The NIR slope is marginally smaller than the optical slope, although the derived slopes and intercepts for both  $L-Z$  relations are consistent with each other.

Variations in the stellar mass-to-light ratio can be responsible for some or all of the scatter in the  $L-Z$  relation. Moreover, the optical luminosity of a fainter galaxy is affected more by a burst of new star formation than the luminosity of a brighter galaxy. Skillman et al. (1997) proposed a comparison of the residuals in luminosity against color to test whether variations in the stellar mass-to-light ratio were the main cause of the scatter. A limited set of data at the time were plotted against optical  $B-V$  color, and were suggestive of a correlation between the residuals in  $B$  luminosity versus  $B-V$ .

We show now that the scatter in the  $L-Z$  relation diminishes when luminosities are measured at longer wavelengths. Residuals in oxygen abundance are plotted against  $B$  and  $[4.5]$  absolute magnitude in the top and bottom panels, respectively, of Fig. 6. The dispersions in the optical and NIR  $L-Z$  relations are 0.161 dex and 0.122 dex, respectively. The scatter in the NIR  $L-Z$  relation is reduced compared to the optical  $L-Z$  relation. The dispersion in the  $L-Z$  relation was *expected* to decrease at longer wavelengths, as NIR luminosities are less

sensitive to extinction by dust and variations in the present-day SFR.

The smaller slope and the reduced dispersion in the NIR are in agreement with the results for star-forming galaxies in the field reported by Salzer et al. (2005). Higher-luminosity and higher-mass galaxies contain more metals and more dust (e.g., Rosenberg et al. 2006); these galaxies would be optically underluminous, which would yield a steeper slope in the optical  $L-Z$ . The effects of absorption by dust vary from galaxy to galaxy, which introduces greater overall scatter in the optical  $L-Z$ . Absorption by dust is mitigated in the NIR, which produces an  $L-Z$  relation with a shallower slope and less scatter. For our present sample of dwarf galaxies, we have assumed that dust is less important (see § 1) than the variations in stellar mass-to-light ratios.

We now examine residuals in oxygen abundance and luminosity against  $B - [4.5]$  color. The results are shown in Fig. 7. Residuals in oxygen abundance from the  $B$   $L-Z$  relation are correlated with color in the sense that redder galaxies have larger abundances compared to the best fit. On the other hand, there is very little to no trend with color for the residuals from the  $[4.5]$   $L-Z$  relation. Residuals in magnitude from the optical and infrared  $L-Z$  relations exhibit similar behavior as above; redder galaxies are fainter in  $B$  and no trend is found at  $4.5 \mu\text{m}$ . The plots in Fig. 7 clearly show that the dispersion is clearly reduced at NIR wavelengths.

We compare in Table 2 the  $4.5 \mu\text{m}$   $L-Z$  relation with recent optical and NIR  $L-Z$  relations from the literature. The slopes from our optical and NIR relations are smaller than values derived from similar relations for other samples of nearby dwarf galaxies. In addition to listing the slope and intercept values for each  $L-Z$  relation, we have also computed the oxygen abundance from the specified relation at a fiducial galaxy luminosity equal to  $M_\lambda = -16$ . The key result from the comparison is that our NIR  $L-Z$  relation exhibits the smallest dispersion.

#### 4. STELLAR MASS-METALLICITY RELATION

The NIR  $L-Z$  relation reflects a fundamental relation between underlying stellar mass and metallicity, and thus, NIR luminosities of dwarf galaxies can directly be related to the mass of their stellar populations (e.g., Vaduvescu et al. 2005). First, to derive the  $4.5 \mu\text{m}$  luminosity in solar units, we have assumed that the absolute magnitude of the Sun is  $+3.33$  in  $K$  (Bell & de Jong 2001), and that the ground-based  $K-M$  color<sup>9</sup> is about 0 for a G2 dwarf star (e.g., Bessell & Brett 1988). Thus, we assume that the absolute magnitude of the Sun at  $4.5 \mu\text{m}$  is  $\simeq +3.3$ . Even if the NIR luminosity is dominated by giant stars, the most extreme  $K-[4.5]$  colors are between  $+0.1$  and  $-0.1$ . As we show below, a non-zero  $K-[4.5]$  color introduces a zero-point offset in the  $M_*-Z$  relation.

We consider an appropriate stellar mass-to-NIR-light ratio. We first assumed a constant stellar mass-to- $[4.5]$ -light ratio of 0.5, as motivated by models for the formation of disk galaxies (e.g., van den Bosch 2002). This value of the stellar mass-to-light ratio is assumed to be independent of color. The resulting fit to the stellar mass-metallicity relation is  $12 + \log(\text{O}/\text{H}) = (5.26 \pm 0.27) + (0.332 \pm 0.033) \log M_*$ , and the resulting dispersion is 0.125 dex. However, stellar mass-to-light ratios can vary by a factor of  $\sim 2$ , even at NIR wavelengths (e.g., Bell & de Jong 2001). Fortunately, stellar mass-to-NIR light

<sup>6</sup> Analytical expressions for the calibration are found in Kobulnicky et al. (1999). Measurements of [N II]/[O II] ( $\lesssim 0.1$ ) break the double-valued degeneracy and point to the “lower branch,” which is appropriate for dwarf galaxies; see H. Lee & Skillman (2004) for additional discussion.

<sup>7</sup> The code is available from STATCODES: <http://www.astrostatistics.psu.edu/statcodes/>.

<sup>8</sup> For each fit, we perform 10000 “bootstrap” simulations to converge onto a solution with the appropriate errors.

<sup>9</sup> We assume that the effective wavelength of  $M$  is  $4.8 \mu\text{m}$  (Campins et al. 1985).

ratios are not strongly dependent upon the age of the dominant stellar population.

For the next step, we derived stellar mass-to-light ratios by accounting for color variations. We used the models by Bell & de Jong (2001, their Tables 3 & 4), where the authors developed methods to derive better estimates of stellar mass in disk galaxies and to determine the baryonic Tully-Fisher relation. For each model in Bell & de Jong (2001), we derived a mass-to-light ratio as a linear function of  $B-K$  color, and computed the stellar mass for each galaxy. Using the color-based functions for  $B-V$  and  $V-K$ , we applied a simple linear combination to obtain the stellar mass-to-light ratio as a linear function of  $B-K$  color. We write

$$\log(M_*/L_K) = a' + b'(B-K), \quad (3)$$

where  $a'$  and  $b'$  are given in Table 3, and  $B-K = (B-[4.5]) - (K-[4.5])$  using our measured  $B-[4.5]$  colors. For a small sample of late-type galaxies, Pahre et al. (2004) determined  $K-[4.5]$  in the range between  $-0.1$  and  $+0.4$ . We adopt here  $K-[4.5] = +0.2$ , and subsequent stellar masses are  $0.15$  to  $0.16$  dex smaller than stellar masses derived with  $K-[4.5] = 0$ .

We obtain stellar masses with

$$\begin{aligned} \log M_* &= \log(M_*/L_K) + \log L_K \\ &= \log(M_*/L_K) + [\log L_{[4.5]} - 0.4(K-[4.5])], \end{aligned} \quad (4)$$

with the stellar mass-to-light ratio defined above. With this empirical prescription for stellar masses, we subsequently performed a  $M_*$ - $Z$  fit to each model. The results are shown in Table 3. Although stellar masses for a given galaxy can vary by as much as  $\sim 0.5$  dex from model-to-model, the subsequent  $M_*$ - $Z$  fits spanning a range of about four decades in stellar mass are similar for all models. The  $M_*$ - $Z$  slopes for models at subsolar metallicity are marginally smaller than the scaled Salpeter stellar initial mass function (IMF) models at solar metallicity.

For this work, we used model 8 in Table 3 (Salpeter IMF, subsolar metallicity) and Equations (3) and (4) to derive initial stellar masses. We then subtracted  $0.25$  dex from all of the stellar masses to scale the masses from the Salpeter (1955) IMF to the Chabrier (2003) IMF. Tremonti et al. (2004) used the Kroupa (2001) IMF to derive stellar masses, which are about  $0.30$  dex smaller than masses derived with the Salpeter IMF; Bell et al. (2003) provide additional discussion on using different IMFs to derive stellar masses in late-type galaxies. We adopt the errors in  $[4.5]$  absolute magnitude as the errors in the logarithm of the stellar mass. We note that our derived stellar mass for NGC 6822,  $\log(M_*/M_\odot) = 8.10$ , is consistent with the value  $(8.24)$  derived from an independent model describing the photometric and chemical evolution (Carigi et al. 2006).

The final  $M_*$ - $Z$  relation is expressed as

$$12 + \log(O/H) = (5.65 \pm 0.23) + (0.298 \pm 0.030) \log M_*. \quad (5)$$

The dispersion is  $0.117$  dex. In Fig. 8, we show the data and the fit expressed by Equation (5) in panel (a). We find an excellent correlation between oxygen abundance and stellar mass; the Pearson correlation coefficient is  $r = +0.90$ . No trend is seen in a plot of the residuals in oxygen abundance from the  $M_*$ - $Z$  relation against stellar mass in panel (b).

We compare our  $M_*$ - $Z$  relation with the relation recently derived for massive galaxies. Tremonti et al. (2004) derived the  $M_*$ - $Z$  relation for over 53000 massive star-forming galaxies at redshifts  $z \lesssim 0.1$  from the Sloan Digital Sky Survey

(SDSS). In Fig. 9, we show the full range in both axes, spanning over two orders of magnitude in oxygen abundance, and five orders of magnitude in stellar mass. The data presented here extend the SDSS  $M_*$ - $Z$  relation to lower masses by roughly  $2.5$  dex. The dispersion for our  $M_*$ - $Z$  relation is comparable to that of the SDSS  $M_*$ - $Z$  relation ( $\approx 0.1$  dex). If dwarf galaxies have insufficient total masses to retain ejecta from supernovae, we expect that the dispersions in both  $L$ - $Z$  and  $M_*$ - $Z$  relations should increase with decreasing luminosity and mass. We will discuss the implications of our  $L$ - $Z$  and  $M_*$ - $Z$  results in § 7.

The polynomial fit to the SDSS galaxies is effective in the mass range between  $10^{8.5}$  and  $10^{11.5} M_\odot$ , whereas our relation overlaps the SDSS relation in the mass range between  $10^{8.5}$  and  $10^{9.5} M_\odot$ . At these stellar masses, SDSS galaxies are about  $0.2$ – $0.3$  dex more metal-rich than the present sample of dwarf galaxies. We describe here the most likely reasons for the offset; see also Savaglio et al. (2005). First, SDSS fiber spectra preferentially sample the inner  $\approx 25\%$  of galaxies (Tremonti et al. 2004). Given that nearby spirals exhibit radial metallicity gradients (e.g., Zaritsky et al. 1994), derived abundances from SDSS spectra might be too high for a number of the galaxies. Second, oxygen abundances for the SDSS data were derived using bright-line methods in the absence of the temperature-sensitive [O III]  $\lambda 4363$  emission line. Recent work with nearby spiral galaxies has shown that bright-line oxygen abundances overestimate the true oxygen abundances by roughly  $0.2$  to  $0.3$  dex at metallicities solar and above (e.g., Stasińska 2002; Kennicutt et al. 2003a; Bresolin et al. 2004). These effects together can account for the offset between the present sample of dwarf galaxies and the SDSS sample of higher-mass galaxies.

Fig. 9 suggests two intriguing possibilities: (a) over a large range in mass ( $\approx 5.5$  dex) there is a single and continuous  $M_*$ - $Z$  relation which turns over or flattens at high galaxy mass, or (b) the  $M_*$ - $Z$  relations describing dwarf and giant galaxies may have different slopes; this possibility has also been suggested by e.g., Salzer et al. (2005); Rosenberg et al. (2006). It will be very interesting to investigate whether slopes of the  $L$ - $Z$  and  $M_*$ - $Z$  relations exhibit a “break” at some characteristic luminosity and mass, respectively<sup>10</sup>.

In Table 4, we list the  $M_*$ - $Z$  relation from the present work, as well as other relations from the literature. With increasing numbers of intermediate- and high-redshift galaxies with measured luminosities and abundances, the interpretation of the  $M_*$ - $Z$  relation for massive systems at distant epochs will depend upon the specific bright-line calibration used to derive oxygen abundances. Although selection criteria and the methods used to derive masses and metallicities may vary, comparisons which begin to tie relations between high-mass and low-mass galaxies and between local and distant galaxies may help illustrate processes acting on galaxies over a range in mass and redshift.

## 5. RELATIONS WITH GAS-TO-STELLAR MASS RATIO

We consider the gas-to-stellar mass ratio, which is representative of the baryonic gas fraction (e.g., Garnett 2002;

<sup>10</sup> Examination of the latest SDSS data ( $\sim 80000$  objects in DR4; C. Tremonti, personal communication) shows that the subsequent  $M_*$ - $Z$  fit is effective to another  $0.5$  dex lower in mass to  $\log(M_*/M_\odot) \sim 8$ . Despite the different methods by which stellar masses and oxygen abundances have been determined, there appears to be good agreement at  $\log(M_*/M_\odot) \sim 8$  between the upper-end of our  $M_*$ - $Z$  relation and the lower-end of the SDSS  $M_*$ - $Z$  relation.

H. Lee et al. 2003b; Skillman et al. 2003; van Zee & Haynes 2006). These parameters reveal important information about the conversion of gas into stars and metals, and about possible gas flows. Assuming zero gas flows and instantaneous recycling, the closed-box model of chemical evolution predicts the metallicity by mass  $Z$  (Schmidt 1963; Searle & Sargent 1972)

$$Z = y \ln \mu^{-1}, \quad (6)$$

where  $y$  is the yield and  $\mu = M_{\text{gas}}/(M_{\text{gas}} + M_*)$  is the fraction of total baryonic mass in the form of gas. From the equation above, we can derive the oxygen abundance by number

$$12 + \log(\text{O}/\text{H}) = 12 + \log(y_{\text{O}}/\zeta) + \log(\ln[1 + (M_{\text{gas}}/M_*)^{-1}]), \quad (7)$$

where  $y_{\text{O}}$  is the oxygen yield by mass,  $\zeta = 11.728$  is the factor to convert abundance by mass to abundance by number,  $M_{\text{gas}} = 1.36 M_{\text{HI}}$  is the total gas mass (which includes helium), and  $M_{\text{gas}}/M_*$  is the gas-to-stellar mass ratio, which is independent of distance.

All of the galaxies in the present sample have direct measures of their H I gas content. We have adopted 21-cm flux integrals from the catalog by Karachentsev et al. (2004). However, we have not scaled the H I mass to the spatial extent of the optical or NIR luminosity (re. stellar mass)<sup>11</sup>. The 21-cm flux integrals and the derived gas-to-stellar mass fractions are listed in Table 5.

The results are shown in Fig. 10. In panel (a), we have plotted oxygen abundances against the gas-to-stellar mass ratio, and the subsequent least-squares fit with the bisector method. The fit is shown as a solid line, and is expressed as

$$12 + \log(\text{O}/\text{H}) = (8.21 \pm 0.07) + (-0.435 \pm 0.085) \log(M_{\text{gas}}/M_*). \quad (8)$$

The dispersion is 0.24 dex. In the center panel (b), we have plotted outflow models as variations of the closed-box model; we assume negligible inflow of metal-poor gas. The purple and blue set of curves, respectively, describe  $y_{\text{O}} = 0.01$  (Tremonti et al. 2004) and  $y_{\text{O}} = 2 \times 10^{-3}$  (H. Lee et al. 2003b; van Zee & Haynes 2006). For each set of curves, the outflow rates from right to left are 0, 5, 10, 25, and 50 times the star-formation rate. These results suggest reduced yields and/or significant outflow rates, which previous authors (e.g., Garnett 2002; van Zee & Haynes 2006) have also indicated.

In Fig. 10c, we have plotted the  $B-[4.5]$  color against the gas-to-stellar mass ratio, where there is a very clear correlation. We first point out three outliers in the data. At  $B-[4.5] \approx +1$  and  $\log(M_{\text{gas}}/M_*) \approx -0.4$ , NGC 1569 is unusually blue for its gas-to-stellar mass ratio, as this dwarf galaxy is known to have just undergone a very strong burst of star formation (e.g., Israel 1988; Waller 1991). At the other end of the plot ( $B-[4.5] \approx +2$ ,  $\log(M_{\text{gas}}/M_*) \approx +1.5$ ) are DDO 154 and Ho IX. DDO 154 is known to have a very large H I halo (Carignan & Beaulieu 1989; Carignan & Purton 1998). Because Ho IX is situated (in projection) very close to the spiral galaxy M 81, the H I for Ho IX is most likely a part of the overall gas distribution for M 81.

The bisector fit to the data (excluding DDO 165, Ho IX, and

NGC 1569) is shown as a solid line, and is expressed as

$$(B-[4.5]) = (2.79 \pm 0.11) + (-0.89 \pm 0.13) \log(M_{\text{gas}}/M_*), \quad (9)$$

and the dispersion in color is 0.32 mag. The fit also implies that  $L_B/L_{[4.5]} \propto (M_{\text{gas}}/M_*)^{0.36}$ . The strong correlation may simply reflect a more dominant process of the conversion of gas into stars. Galaxies with lower gas-to-stellar mass ratios have already depleted their fuel, and appear redder when present-day star formation no longer becomes active.

We consider possible departures from the closed-box model by inverting Equation (6) to obtain the effective yield,  $y_{\text{eff}} = Z/\ln(\mu^{-1})$ . The effective yield is determined simply from the measured oxygen abundances and baryonic gas fractions, and is equal to the true yield when the closed-box assumption applies. Effective yields which are smaller than the true yield suggest either outflow or infall of metal-poor gas (e.g., Edmunds 1990; Dalcanton 2006; van Zee & Haynes 2006). We have listed derived values of the effective yield in Table 5.

In Fig. 11a, we plot the effective yield as a function of the total baryonic mass, following Fig. 8 in Tremonti et al. (2004); Garnett (2002) also obtained a similar plot for a sample of nearby spiral and irregular galaxies. The empirical fit obtained by (Tremonti et al. 2004) is based upon the premise that galactic winds were responsible for metals loss; see also Veilleux et al. 2005 for additional discussion. From the present sample, there are dwarf galaxies with effective yields about a factor of ten lower than the “asymptotic” yield ( $\log y_{\text{eff}} \approx -1.98$ ) for more massive galaxies in the SDSS. We have also marked for comparison the solar oxygen mass fraction ( $\log Z_{\text{O},\odot} = -2.27$ , Asplund et al. 2004; Meléndez 2004) and the effective yield for the nearby spiral M51 ( $\log y_{\text{eff}} = -2.49$ , Bresolin et al. 2004)<sup>12</sup>. Accounting for the  $\sim 0.2$ – $0.3$  dex offset described above in § 4 lowers the “asymptotic” yield in better agreement with the solar mass fraction and the effective yield for M51. We note that these values are also comparable to the range of effective yields for dwarf galaxies (e.g.,  $\log y_{\text{eff}} \approx -2.7$  to  $-2.1$ ) previously reported by, e.g., H. Lee et al. 2003b; van Zee & Haynes 2006).

Although there may be a trend between yield and baryonic mass for the low-mass galaxies, there is however large scatter, which is about 1.5 dex at  $\sim 10^{8.5} M_{\odot}$ . Three galaxies with the largest effective yields ( $\log y_{\text{eff}} \gtrsim -2$ ) in our sample are DDO 154, NGC 3109, and Sextans A. However, their measured luminosities and abundances are in good agreement with other galaxies at comparable abundances and luminosities, respectively.

van Zee & Haynes (2006) observed a trend between effective yield and H I-gas-to- $B$ -light ratio for a sample of nearby UGC dwarf galaxies, where the H I-gas-to- $B$ -light ratio was a measure of the gas-to-stellar mass ratio. These authors ruled out infall of metal-poor gas as a mechanism to decrease effective yields (see also Dalcanton 2006). In Fig. 11b, we plot the effective yield as a function of the gas-to-stellar mass ratio. Gas-rich systems eventually reach the “asymptotic” yield, while gas-poor systems have lower effective yields. The effective yield is correlated with the gas-to-stellar mass ratio, and the fit is expressed as

$$\log y_{\text{eff}} = (-2.75 \pm 0.06) + (0.700 \pm 0.057) \log(M_{\text{gas}}/M_*) \quad (10)$$

<sup>11</sup> The proper interpretation of effective yields with respect to the “inner” and “outer” gas relative to the optical extent depends very strongly on the assumed metallicity of the outer gas, which is not known or well constrained in many nearby dwarf galaxies; however, see, e.g., Skillman et al. (1989); Kennicutt & Skillman (2001); Garnett (2002) for additional discussion. A detailed comparison between “non-scaled” and “scaled” H I content relative to the optical extent is outside the present focus of this paper.

<sup>12</sup> For a sample of H II regions in M51, Bresolin et al. (2004) measured electron temperatures from [N II]  $\lambda 5755$  measurements, and derived chemical abundances. The subsequent effective yield for M51 was found to be lower by a factor of four than previous estimates.

with dispersion in log yield equal to 0.22 dex. In the limit of high gas fraction, the closed-box model predicts that the slope in equation above is equal to one.

## 6. RELATIONS WITH ROTATION VELOCITY

For a sample of dwarf irregular and spiral galaxies, Garnett (2002) found a relationship between metallicity and rotation velocity with an apparent “break” in the relation at  $120 \text{ km s}^{-1}$ . Pilyugin et al. (2004) performed a homogeneous analysis using his bright-line calibration, and found a similar break at  $80 \text{ km s}^{-1}$ . We plot various quantities against HI rotational velocity in Fig. 12, where the range of velocities for the present sample is between 10 and  $80 \text{ km s}^{-1}$ ; see Table 1. As an alternative to velocity on a linear scale, we plot the *logarithm* of the velocity.

In Fig. 12a, there appears to be a good correlation between stellar mass and rotation velocity ( $r = +0.66$ ), although there is a paucity of data at low rotation velocity. The bisector fit is

$$\log M_* = (4.14 \pm 0.57) + (2.33 \pm 0.36) \log v_{\text{rot}}, \quad (11)$$

and the dispersion in log stellar mass is 0.63 dex. The fit can be inverted to give  $v_{\text{rot}} \propto M_*^{0.43}$ ; the numerical exponent here is larger than the predicted value of 0.2 (Dekel & Woo 2003) by  $3.4\sigma$ . The observational result suggests either larger rotation velocities at a given stellar mass, or smaller stellar masses at a given velocity.

In panels (b) and (c), respectively, we have plotted the gas-to-stellar mass ratio and the effective yield against rotation velocity. Neither panel reveals a strong trend, although the effective yield appears to rise slightly with rotation velocity. The rise of the effective yield with rotation velocity has been discussed by Garnett (2002), Pilyugin et al. (2004), and Dalcanton (2006). Galaxies with  $v_{\text{rot}} \gtrsim 100 \text{ km s}^{-1}$  have effective yields approaching that of the asymptotic yield. Less massive galaxies with  $v_{\text{rot}} \lesssim 100 \text{ km s}^{-1}$  have smaller effective yields which are roughly consistent with a solar-type yield, as seen above in Fig. 11. The present work suggests that the effective yield may be roughly constant, or at the very least, is weakly dependent upon rotation velocity. While additional data are required for confirmation, this result suggests that within the mass range of dwarf galaxies, the effective yield depends more strongly upon the relative gas fraction than upon rotation velocity.

## 7. DISCUSSION

We have shown that the scatter in the optical  $L-Z$  relation is constant ( $\sim 0.16$  dex) over a range of 11 mag in  $B$  luminosity, and the scatter decreases to 0.12 dex over 8 mag at NIR wavelengths. Our subsequent stellar mass-metallicity relation extends the dynamic range of the SDSS  $M_*-Z$  relation to lower masses by roughly 2.5 dex. We have also shown that the scatter for the  $M_*-Z$  relation appears to be similar over 5.5 orders of magnitude in stellar mass.

Models of galaxy formation have been successful in predicting the slopes of the  $L-Z$  and  $M_*-Z$  relations. These models generally incorporate feedback, which describes how effectively massive stars can inject energy into the surrounding interstellar medium. Dekel & Silk (1986) predicted the scaling relation,  $L \propto Z^{2.7}$ , for dwarf galaxies formed and embedded within dark matter haloes, although their model is less applicable to dwarf galaxies which have undergone a low and constant level of star formation over a Hubble time. The derived slopes of the  $L-Z$  relations (our Equation 2) are in

approximate agreement with the Dekel & Silk (1986) prediction, although our  $[4.5] L-Z$  slope is smaller than the predicted value by about  $2\sigma$ . Recently, Dekel & Woo (2003) predicted the scaling relation  $Z \propto M_*^{0.4}$ . The slope of the  $M_*-Z$  relation in Equation (5) is smaller than the predicted value by  $3.4\sigma$ . We note, however, that the Dekel & Woo (2003) scaling relation was derived for stellar iron metallicities under the assumption of constant  $[\text{Fe}/\text{O}]$ , which may not be applicable in dwarf irregular galaxies (e.g., Smith et al. 2002).

Somerville & Primack (1999) compared predicted  $L-Z$  relations among a number of semi-analytical models. Although the details varied with the specific feedback recipe within the models, the scatter in the  $L-Z$  relations increased with decreasing total luminosity (their Fig. 18). Unfortunately, none of the models provided acceptable fits to all of the known observational parameters, and these authors stated that the failure of the models is likely caused by a strong difference in efficiency between ejecting gas and ejecting metals.

Models by De Lucia et al. (2004) produced  $M_*-Z$  relations consistent with the SDSS  $M_*-Z$  relation over a similar range in stellar mass, down to  $\log (M_*/M_\odot) \sim 8.5$ . Robertson et al. (2005) developed models to describe chemical abundance patterns observed in the Galactic halo, Local Group dwarf spheroidals, and Local Group dwarf irregular galaxies. They incorporated chemical enrichment histories and various gas accretion histories within cosmologically motivated  $\Lambda$ CDM models for the formation of dwarf galaxies and the Galactic stellar halo. Their models were able to reproduce the Dekel & Woo (2003) scaling relation and the observed abundance patterns in nearby dwarf galaxies.

Tremonti et al. (2004) explained that the relationship between stellar mass and metallicity was a consequence of the relationship between effective yield and total baryonic mass. That is, higher-mass systems are able to convert gas into stars which produce galaxies with large stellar masses and metallicities; whereas, lower-mass systems convert less gas into stars, and lose their metals as outflows by virtue of the lower total masses. These authors state: “... It is our view that the strong positive correlation between effective yield and baryonic mass is most naturally explained by the increasing potential barrier that the metal-laden wind must overcome to achieve ‘blowout.’ ...” In fact, since a number of the low-mass galaxies in our sample do not depart significantly from the  $L-Z$  and  $M_*-Z$  relationships and have effective yields close to or exceeding the asymptotic value, it is difficult to explain these relationships as a result of very disruptive blowout events.

Present-day galactic winds removing material from low-mass galaxies should have dramatic effects on the properties of such systems. We consider a prototype dwarf starburst galaxy, NGC 1569, which is undergoing blowout. Martin et al. (2002) showed in their *Chandra* observations that most of the oxygen produced in the starburst is in the enriched outflow. However, the results from (Martin et al. 2002, their Table 6) and Angeretti et al. (2005) reveal that at most 2% of the stellar mass is produced in the burst. Although the stellar mass ( $\approx 10^{8.5} M_\odot$ ) of NGC 1569 is at the upper end of the range for our sample of dwarf galaxies, an equivalent NGC 1569-like burst would produce a more significant amount of stars in lower-mass systems. However, this high level of star formation is not presently seen in the other low-mass galaxies from our nearby sample, and certainly not seen in dwarf irregulars within the Local Group (cf. Mateo 1998).

NOTE. — Col. (1): Reference. Col. (2): Number of galaxies. Col. (3): Luminosity range. A number of the studies quote  $B, AB$  magnitudes, which are 0.163 mag brighter than Johnson  $B$  magnitudes (Frei & Gunn 1994). Col. (4): Wavelength. Cols. (5) and (6): Fits to the respective relations are expressed as  $12+\log(\text{O}/\text{H}) = a + bM_\lambda$ , where  $a$  and  $b$  are the intercept and the slope, respectively, and  $M_\lambda$  is the absolute magnitude at wavelength  $\lambda$ . Col. (7):  $a_{16}$  represents the oxygen abundance determined from the specified relation at a fiducial galaxy luminosity equal to  $M_\lambda = -16$ . Col. (8): Dispersion in oxygen abundance.

<sup>a</sup> Richer & McCall (1995) stated the fit parameters and resulting dispersion were effective only for galaxies brighter than  $M_B = -15$ , as the dispersion increased towards lower luminosities. However, H. Lee et al. (2003b) showed that improved data (e.g., distances) reduced the dispersion at lower luminosities.

<sup>b</sup> Tremonti et al. (2004) obtained galaxy luminosities in Sloan filter  $g$  (similar to  $B$ ), and accounted for the appropriate transformations from  $g$  to  $B$ .

TABLE 3

STELLAR MASSES USING MODELS OF STELLAR MASS-TO-LIGHT RATIOS FROM TABLES 3 AND 4 IN BELL & DE JONG (2001) AND THE METHOD DESCRIBED IN § 4. FROM THE RESULTING DERIVED STELLAR MASSES, WE PERFORMED THE RESULTING  $M_*$ - $Z$  FIT FOR EACH MODEL. WE LIST EACH  $M_*$ - $Z$  FIT AS  $12+\log(\text{O}/\text{H}) = a + b \log M_*$ , AND WE LIST THE DISPERSION IN OXYGEN ABUNDANCE FOR EACH FIT.

TABLE 4

COMPARISON AMONG SELECTED STELLAR MASS-METALLICITY RELATIONS FOR NEARBY DWARF IRREGULAR GALAXIES AND STAR-FORMING GALAXIES AT DISTANT EPOCHS. FITS TO THE RESPECTIVE RELATIONS ARE EXPRESSED AS  $12+\log(\text{O}/\text{H}) = f(X)$ , OR FUNCTIONS OF  $X = \log M_*$ . WE HAVE NOT HOMOGENIZED MEASURES OF THE STELLAR MASS OR METALLICITY FOR THE OTHER STUDIES. THIS IS NOT A COMPLETE LISTING, AS WE HAVE SELECTED RECENTLY PUBLISHED  $M_*$ - $Z$  RELATIONS FROM THE LITERATURE.

NOTE. — Col. (1): Galaxy name. Col. (2): 21-cm flux densities (Karachentsev et al. 2004). Col. (3): Gas-to-stellar mass ratio. Col. (4): Logarithm of the effective yield. Col. (5): H I rotational velocity corrected for inclination and turbulent motions (Karachentsev et al. 2004).

FIG. 1.— Postage-stamp images at  $4.5\ \mu\text{m}$  of dwarf galaxies from GTO 128. North and East are at the top and left, respectively, in each frame. All galaxies are displayed with the same isophotal scaling to emphasize the large range in surface brightness of the dwarf galaxies. The fields of view shown are: GR 8 —  $5' \times 5'$ , IC 1613 —  $10' \times 10'$ , IC 5152 —  $5' \times 5'$ , Leo A —  $5' \times 5'$ , NGC 55 —  $15' \times 10'$ , NGC 3109 —  $10' \times 5'$ , Peg DIG —  $5' \times 5'$ , Sextans A —  $5' \times 5'$ , Sextans B —  $5' \times 5'$ , and WLM —  $5' \times 15'$ .

FIG. 2.— Example of galaxy photometry for Sextans B. North and East are to the top and left, respectively, in the  $4.5\ \mu\text{m}$  image. The central elliptical aperture surrounds the galaxy, and the seven circular apertures sample the background flux. The galaxy aperture is aligned roughly to the same orientation as the optical emission seen on images from the Digitized Sky Survey.

FIG. 3.— Comparison of total  $4.5\ \mu\text{m}$  fluxes for selected dwarf galaxies from the SINGS sample: fluxes from Dale et al. (2005) versus measured fluxes from the present work. The dotted line marks the line of equal fluxes.

FIG. 4.— (a)  $B$  absolute magnitude versus [4.5] absolute magnitude. Lines of constant  $B-[4.5]$  color between 0 and 4 are also plotted. (b)  $B-[4.5]$  color versus [4.5] absolute magnitude. The Pearson correlation coefficient for this color-magnitude relation is  $r = -0.24$ .

FIG. 5.— Nebular oxygen abundances versus (a) absolute magnitude in  $B$ , and (b) absolute magnitude at 4.5  $\mu\text{m}$ . The solid lines represent fits to the data, whose fit parameters are given in each panel. The Pearson coefficients are  $r = -0.80$  in  $B$ , and  $r = -0.89$  in [4.5].

FIG. 6.— (a) Residuals in oxygen abundance (from  $B$  fit) versus  $B$  absolute magnitude. (b) Residuals in oxygen abundance (from  $[4.5]$  fit) versus  $[4.5]$  absolute magnitude. Both panels are plotted to the same vertical scale, and a short-dashed horizontal line in each panel indicates zero residual. The dotted horizontal lines in each panel indicate the  $1\sigma$  scatter. The scatter in the NIR  $L-Z$  relation is reduced compared to that found in the  $B L-Z$  relation.

FIG. 7.— Panel (a): Residuals in oxygen abundance from the  $B L-Z$  fit versus  $B-[4.5]$  color. Panel (b): Residuals in oxygen abundance from the  $[4.5] L-Z$  fit versus  $B-[4.5]$  color. Panels (a) and (b) are plotted to the same vertical scale. Panel (c): Residuals in  $B$  absolute magnitude from the  $B L-Z$  fit versus  $B-[4.5]$  color. Panel (d): Residuals in  $[4.5]$  absolute magnitude from the  $[4.5] L-Z$  fit versus  $B-[4.5]$  color. Panels (c) and (d) are plotted to the same vertical scale. Residuals at optical wavelengths correlate ( $r = +0.67$ ) more strongly with  $B-[4.5]$  color than residuals at NIR wavelengths ( $r = +0.28$ ).

FIG. 8.— Panel (a): oxygen abundance versus stellar mass. Stellar masses have been derived using the color-based stellar mass-to-light ratios from model 8 in Table 3, and have been corrected to the Chabrier (2003) IMF. The fit to the data is shown as the solid line; the Pearson coefficient is  $r = +0.90$ . Panel (b): residuals in oxygen abundance from our present  $M_*$ -Z relation against stellar mass. The Pearson coefficient is  $r = -0.08$ .

FIG. 9.— Oxygen abundance versus stellar mass. The plot has been expanded to include more massive galaxies. Data and the least-squares fit to the present data from Fig. 8 are shown; the fit is shown as a thin black solid line and is arbitrarily extrapolated to  $10^{10} M_\odot$ . The polynomial fit to over 53000 galaxies from the SDSS (Tremonti et al. 2004) is shown as a heavy red solid line; the  $1\sigma$  curves are also shown. Their fit is effective over the mass range between  $8.5 \lesssim \log(M_*/M_\odot) \lesssim 11.5$ . In the “overlap region” ( $8.5 \lesssim \log(M_*/M_\odot) \lesssim 9.5$ ), SDSS galaxies are more metal-rich by  $\approx 0.2$ – $0.3$  dex compared to dwarf galaxies in the present sample. An extrapolation of the SDSS  $M_*$ -Z relation down to  $\log(M_*/M_\odot) = 7.5$  is shown as a blue short-dashed line.

FIG. 10.— Panels (a) and (b): oxygen abundances are plotted against gas-to-stellar mass ratio. In panel (a), the solid line represents the fit to the data; the Pearson coefficient is  $r = -0.58$ . In panel (b), we have plotted outflow variations of the closed-box model, where the outflow rate is a constant multiple of the star-formation rate. The purple and blue curves describe models with  $y_O = 0.01$  (Tremonti et al. 2004) and  $y_O = 2 \times 10^{-3}$  (e.g., H. Lee et al. 2003b; van Zee & Haynes 2006), respectively. For each set of curves, the outflow rates from right to left are 0, 5, 10, 25, and 50 times the star-formation rate, respectively. In panel (c),  $B-[4.5]$  colors are plotted against gas-to-stellar mass ratio. The solid line represents the fit, and the Pearson coefficient is  $r = -0.83$ . The fit excludes DDO 165, Ho IX, and NGC 1569; the latter is the outlier with a very blue color for its relatively low gas-to-stellar mass ratio.

FIG. 11.— Panel (a): effective yield against total baryonic mass in gas and stars; cf. also Garnett (2002). Filled circles represent dwarf galaxies in the present work. Crosses represent the median of the SDSS data in mass bins of 0.1 dex (Tremonti et al. 2004). The empirical fit is shown as a thin solid line (Tremonti et al. 2004, their Equation 6). The asymptotic yield ( $y_{\text{eff}} = 0.0104$ ) is represented by the short-dashed line. The solar oxygen mass fraction (Asplund et al. 2004; Meléndez 2004) and the effective yield for the nearby spiral galaxy M51 (Bresolin et al. 2004) are represented by dotted and long-dashed lines, respectively. These values are comparable to the range of effective yields for dwarf galaxies (e.g.,  $\log y_{\text{eff}} \simeq -2.7$  to  $-2.1$ , H. Lee et al. 2003b; van Zee & Haynes 2006). Panel (b): effective yield versus gas-to-stellar mass ratio. The fit shown is represented by a thin solid line. The trend here is similar to the one observed for a sample of nearby UGC dwarf galaxies described by van Zee & Haynes (2006). The horizontal lines are the same as in the panel above.

FIG. 12.— Panel (a): stellar mass versus H I rotation velocity. The solid line represents the fit to the data with Pearson coefficient  $r = +0.67$ . Panel (b): gas-to-stellar mass ratio versus H I rotation velocity. Panel (c): effective yield versus H I rotation velocity. H I rotation velocities in Table 1 have been corrected for inclination and turbulent motions; see Karachentsev et al. (2004). The Pearson correlation coefficient between rotation velocity and effective yield is  $r = +0.40$ . The horizontal lines are the same as in Fig. 11.
